Abstract

We consider long-baseline neutrino oscillations in the framework of two schemes with mixing of four massive neutrinos which can accommodate all the existing indications in favour of neutrino mixing. Within these schemes, we derive bounds on the oscillation probabilities and the CP-odd neutrino-antineutrino asymmetries in long-baseline experiments. Using the results of short-baseline neutrino oscillation experiments, we obtain rather strong upper bounds on the long-baseline probabilities $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ and $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$. Nevertheless, the projected sensitivities of the MINOS and ICARUS experiments are better than our bounds. We also show that there are no corresponding constraints for $\nu_\mu \rightarrow \nu_\mu^{(-)}$ and $\nu_\mu \rightarrow \nu_\tau^{(-)}$ long-baseline oscillations and that the CP-odd asymmetry in the latter channel can reach the maximal value $2/3\sqrt{3}$ allowed by the unitarity of the mixing matrix. Some schemes with mixing of three neutrinos are also considered.

I. INTRODUCTION

The search for neutrino oscillations remains a central issue of neutrino experiments. In several short-baseline (SBL) experiments, which are sensitive to relatively large values of the neutrino mass-squared difference δm^2 ($\delta m^2 \gtrsim 0.1 \text{ eV}^2$), different oscillation channels are investigated at present: $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ (LSND [1], KARMEN [2], CCFR [3], NOMAD [4]); $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ (CHORUS [5], NOMAD [6] and CCFR [7]). The long-baseline (LBL) neutrino oscillation experiments which will operate in the near future will be sensitive to much smaller values of δm^2 ($\delta m^2 \gtrsim 10^{-3} \text{ eV}^2$). Long-baseline experiments with reactor antineutrinos are starting to take data (CHOOZ [8]) or are under preparation (Palo Verde [9]). Long-baseline experiments with accelerator neutrinos (KEK-Super-Kamiokande [10], Fermilab-Soudan [11], CERN-Gran Sasso [12]) are under preparation.

No indications in favour of neutrino oscillations have been found in many experiments with terrestrial neutrinos which have been done in the past (see the reviews in Ref. [13]). On the other hand, such indications have been found in all solar neutrino experiments (Homestake, Kamiokande, GALLEX and SAGE [14]). The suppression of the detected event rates with respect to those predicted by the Standard Solar Model (SSM) [15] can be explained with neutrino mixing. In the case of resonant MSW transitions [16], it was found [17] that the oscillation parameters δm^2 and $\sin^2 2\vartheta$ (ϑ is the mixing angle) have the following values:

$$3 \times 10^{-6} \lesssim \delta m^2 \lesssim 1.2 \times 10^{-5} \text{ eV}^2, \quad 4 \times 10^{-3} \lesssim \sin^2 2\vartheta \lesssim 1.2 \times 10^{-2}. \quad (1.1)$$

The solar neutrino puzzle can also be solved by invoking vacuum neutrino oscillations [18], in which case $\delta m^2 \sim 10^{-10} \text{ eV}^2$.

Indications in favour of $\bar{\nu}_\mu \rightarrow \bar{\nu}_x$ oscillations ($x \neq \mu$) have been found also in the Kamiokande [19], IMB [20] and Soudan [21] atmospheric neutrino experiments. From the analysis of the Kamiokande data the following allowed ranges for the oscillation parameters were obtained [19]:

$$5 \times 10^{-3} \lesssim \delta m^2 \lesssim 3 \times 10^{-2} \text{ eV}^2, \quad 0.7 \lesssim \sin^2 2\vartheta \lesssim 1 \quad (\nu_\mu \leftrightarrow \nu_\tau), \quad (1.2)$$

$$7 \times 10^{-3} \lesssim \delta m^2 \lesssim 8 \times 10^{-2} \text{ eV}^2, \quad 0.6 \lesssim \sin^2 2\vartheta \lesssim 1 \quad (\nu_\mu \leftrightarrow \nu_e). \quad (1.3)$$

Finally, indications in favour of $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations have been found recently in the LSND experiment [1], in which antineutrinos originating from the decays of μ^+ 's at rest were detected. From the analysis of the data of this experiment and the negative results of other SBL experiments (in particular, the Bugey [22] and BNL E776 [23] experiments), it follows that

$$0.3 \lesssim \delta m^2 \lesssim 2.2 \text{ eV}^2, \quad 10^{-3} \lesssim \sin^2 2\vartheta \lesssim 4 \times 10^{-2}. \quad (1.4)$$

All the above-mentioned hints for neutrino oscillations can be accommodated in schemes with four neutrinos. These schemes require a sterile neutrino field ($\alpha = s$) in addition to the usual flavour fields with flavours $\alpha = e, \mu, \tau$. The specific nature of such 4-neutrino schemes has recently been derived from the data [24,25].

The purpose of the present paper is to consider LBL neutrino oscillations in the light of the 4-neutrino schemes favoured by the data. In this context we will discuss the bounds on the LBL oscillation probabilities and on the CP-odd neutrino–antineutrino asymmetries that can be obtained from the results of the SBL oscillation experiments. We will also make an excursion to some 3-neutrino schemes.

Let us stress that CP violation is one of the important problems which can be tackled in LBL experiments. If CP is violated in the lepton sector, then the neutrino mixing matrix is complex and the probabilities of $\nu_\alpha \rightarrow \nu_\beta$ and $\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta$ transitions ($\alpha \neq \beta$) are different. The observation of CP violation in neutrino oscillations will be very important for the understanding of the nature of neutrino mixing and the nature of CP violation. In the framework of mixing of three massive neutrinos, possible effects of CP violation in LBL experiments were considered in Refs. [26–28]. In the present paper we will derive bounds on the CP-odd asymmetries in LBL experiments in the framework of the schemes with mixing of four massive neutrinos which take into account all the existing neutrino oscillation data. We will present general methods for obtaining such bounds from the results of SBL experiments. These methods will be applied to some mixing schemes of three neutrinos as well. In the context of the 4-neutrino schemes, we will show that sizable CP-odd asymmetries can be expected only in $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ transitions.

The plan of the paper is as follows. In Section II we will review the basics of neutrino oscillations and CP violation. The 4-neutrino schemes favoured by the data and the relevant LBL formulas are introduced in Section III. Section IV is devoted to the discussion of the bounds on the LBL oscillation probabilities which follow from the 4-neutrino schemes and the SBL data. The same is done for the CP violation parameters in section V. Finally, we make a digression to 3-neutrino schemes in Section VI and we formulate our conclusions in Section VII. The three Appendices contain some derivations and discussions of the bounds used in the main body of the paper.

II. NEUTRINO OSCILLATIONS AND CP VIOLATION

In accordance with the neutrino mixing hypothesis (see, for example, Refs. [29–31]), a left-handed neutrino field $\nu_{\alpha L}$ is a mixture of the left-handed components ν_{kL} of the (Dirac or Majorana) fields of neutrinos with definite masses m_k :

$$\nu_{\alpha L} = \sum_k U_{\alpha k} \nu_{kL} \quad \text{with} \quad \alpha = e, \mu, \tau, s, \dots \quad (2.1)$$

where U is the unitary mixing matrix and ν_{sL} a sterile neutrino field. The mixing in Eq.(2.1) implies that the probabilities of transitions of neutrinos (antineutrinos) with momentum p at a distance L of the neutrino detector from the neutrino source are given by

$$P_{\nu_\alpha \rightarrow \nu_\beta} = \left| \sum_k U_{\beta k} U_{\alpha k}^* \exp\left(-i \frac{\Delta m_{k1}^2 L}{2p}\right) \right|^2, \quad (2.2)$$

$$P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta} = \left| \sum_k U_{\beta k}^* U_{\alpha k} \exp\left(-i \frac{\Delta m_{k1}^2 L}{2p}\right) \right|^2, \quad (2.3)$$

where $\Delta m_{k1}^2 \equiv m_k^2 - m_1^2$ (we take $m_1 < m_2 < \dots$). From Eqs.(2.2) and (2.3) it follows that the transition probabilities of neutrinos and antineutrinos are connected by the relation

$$P_{\nu_\alpha \rightarrow \nu_\beta} = P_{\bar{\nu}_\beta \rightarrow \bar{\nu}_\alpha} . \quad (2.4)$$

This relation reflects CPT invariance.

If CP invariance in the lepton sector holds, then there are phase conventions such that in the case of Dirac neutrinos we have

$$U_{\alpha k} = U_{\alpha k}^* , \quad (2.5)$$

whereas in the case of Majorana neutrinos we have

$$U_{\alpha k} = -U_{\alpha k}^* \eta_k \quad (2.6)$$

where $\eta_k = \pm i$ is the CP parity¹ of the Majorana neutrino with mass m_k (see, for example, Ref. [30]). It is obvious that the CP parities η_k do not enter in the expressions for the transitions amplitudes. Hence, in both the Dirac and Majorana cases, CP invariance implies that [33]

$$P_{\nu_\alpha \rightarrow \nu_\beta} = P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta} . \quad (2.7)$$

Let us introduce the CP-odd asymmetries

$$D_{\alpha;\beta} \equiv P_{\nu_\alpha \rightarrow \nu_\beta} - P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta} . \quad (2.8)$$

From CPT invariance it follows that

$$D_{\alpha;\beta} = -D_{\beta;\alpha} . \quad (2.9)$$

Furthermore, from the unitarity of the mixing matrix we have

$$\sum_{\beta \neq \alpha} D_{\alpha;\beta} = 0 . \quad (2.10)$$

We observe that in the case of transitions among three flavour states (ν_e, ν_μ, ν_τ) the CP asymmetries satisfy the relations [34]

$$D_{e;\mu} = D_{\tau;e} = D_{\mu;\tau} , \quad (2.11)$$

which follow from Eqs.(2.9) and (2.10).

In the general case of mixing of an arbitrary number of massive neutrinos, the asymmetries are given by

$$D_{\alpha;\beta} = 4 \sum_{k>j} \text{Im} [U_{\alpha j} U_{\beta j}^* U_{\alpha k}^* U_{\beta k}] \sin \frac{\Delta m_{kj}^2 L}{2p} . \quad (2.12)$$

Therefore, CP violation in the lepton sector can be observed only if at least one of the oscillating terms in the transition probabilities does not vanish due to the averaging over the neutrino energy spectrum and the size of the neutrino source and detector.

¹ The CP parities of Majorana neutrinos could be important for neutrinoless double beta-decay; for example, if the ν_k 's have different CP parities, their contributions to the amplitude of neutrinoless double-beta decay could cancel each other [32].

III. FOUR MASSIVE NEUTRINOS

All existing indications in favour of neutrino oscillations can be accommodated by a scheme with mixing of four massive neutrinos [35,36,24,25]. In Ref. [24] we have shown that from the six possible spectral schemes of four massive neutrinos, which correspond to three different scales of mass-squared differences Δm_{kj}^2 , only two schemes are compatible with the results of all experiments. In these two schemes the four neutrino masses are divided in two pairs of close masses separated by a gap of ~ 1 eV:

$$(A) \quad \underbrace{\overbrace{m_1 < m_2}^{\text{atm}} \ll \overbrace{m_3 < m_4}^{\text{solar}}}_{\text{LSND}} \quad \text{and} \quad (B) \quad \underbrace{\overbrace{m_1 < m_2}^{\text{solar}} \ll \overbrace{m_3 < m_4}^{\text{atm}}}_{\text{LSND}}. \quad (3.1)$$

In scheme A, Δm_{21}^2 is relevant for the explanation of the atmospheric neutrino anomaly and Δm_{43}^2 is relevant for the suppression of solar ν_e 's. In scheme B, the roles of Δm_{21}^2 and Δm_{43}^2 are reversed.

We will consider first SBL neutrino oscillations in the framework of these two schemes. Let us note above all that it is impossible to reveal the effects of CP violation in these experiments which are sensitive to $\Delta m_{41}^2 \gtrsim 0.1 \text{ eV}^2$. Furthermore, both schemes A and B give the same oscillation probabilities. Therefore, it is impossible to distinguish A from B in SBL oscillation experiments either. In fact, since in these experiments

$$\frac{\Delta m_{21}^2 L}{2p} \ll 1 \quad \text{and} \quad \frac{\Delta m_{43}^2 L}{2p} \ll 1, \quad (3.2)$$

the probabilities of $\nu_\alpha \rightarrow \nu_\beta$ and $\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta$ transitions are equal and are given by [36]

$$P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{SBL})} = \frac{1}{2} A_{\alpha;\beta} \left(1 - \cos \frac{\Delta m^2 L}{2p} \right), \quad (3.3)$$

with $\Delta m^2 \equiv \Delta m_{41}^2 = m_4^2 - m_1^2$ and the oscillation amplitude

$$A_{\alpha;\beta} = 4 \left| \sum_{k=1,2} U_{\beta k} U_{\alpha k}^* \right|^2 = 4 \left| \sum_{k=3,4} U_{\beta k} U_{\alpha k}^* \right|^2. \quad (3.4)$$

The survival probabilities of neutrinos and antineutrinos are given by

$$P_{\nu_\alpha \rightarrow \nu_\alpha}^{(\text{SBL})} = 1 - \sum_{\beta \neq \alpha} P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{SBL})} = 1 - \frac{1}{2} B_{\alpha;\alpha} \left(1 - \cos \frac{\Delta m^2 L}{2p} \right), \quad (3.5)$$

where

$$\begin{aligned} B_{\alpha;\alpha} = \sum_{\beta \neq \alpha} A_{\alpha;\beta} &= 4 \left(\sum_{k=1,2} |U_{\alpha k}|^2 \right) \left(1 - \sum_{k=1,2} |U_{\alpha k}|^2 \right) \\ &= 4 \left(\sum_{k=3,4} |U_{\alpha k}|^2 \right) \left(1 - \sum_{k=3,4} |U_{\alpha k}|^2 \right). \end{aligned} \quad (3.6)$$

Long-baseline neutrino oscillation experiments are planned to be sensitive to the “atmospheric neutrino range” $10^{-3} \text{ eV}^2 \lesssim \Delta m_{kj}^2 \lesssim 10^{-1} \text{ eV}^2$. In scheme A, the probabilities of $\nu_\alpha \rightarrow \nu_\beta$ and $\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta$ transitions in LBL experiments are given by

$$P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL,A})} = \left| U_{\beta 1} U_{\alpha 1}^* + U_{\beta 2} U_{\alpha 2}^* \exp\left(-i \frac{\Delta m_{21}^2 L}{2p}\right) \right|^2 + \left| \sum_{k=3,4} U_{\beta k} U_{\alpha k}^* \right|^2, \quad (3.7)$$

$$P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta}^{(\text{LBL,A})} = \left| U_{\beta 1}^* U_{\alpha 1} + U_{\beta 2}^* U_{\alpha 2} \exp\left(-i \frac{\Delta m_{21}^2 L}{2p}\right) \right|^2 + \left| \sum_{k=3,4} U_{\beta k}^* U_{\alpha k} \right|^2. \quad (3.8)$$

These formulas have been obtained from Eqs.(2.2) and (2.3), respectively, taking into account the fact that in LBL experiments $\Delta m_{43}^2 L/2p \ll 1$ and dropping the terms proportional to the cosines of phases much larger than 2π ($\Delta m_{kj}^2 L/2p \gg 2\pi$ for $k = 3, 4$ and $j = 1, 2$). Such terms do not contribute to the oscillation probabilities averaged over the neutrino energy spectrum. The transition probabilities in scheme B ensue from the expressions (3.7) and (3.8) with the change

$$1, 2 \leftrightarrow 3, 4. \quad (3.9)$$

From Eqs.(3.7), (3.8) and (3.9) it follows that the LBL CP-odd asymmetries $D_{\alpha;\beta}^{(\text{LBL})}$ in the schemes A and B are given by

$$D_{\alpha;\beta}^{(\text{LBL,A})} = I_{\alpha\beta}^{(\text{A})} \sin \frac{\Delta m_{21}^2 L}{2p}, \quad (3.10)$$

$$D_{\alpha;\beta}^{(\text{LBL,B})} = I_{\alpha\beta}^{(\text{B})} \sin \frac{\Delta m_{43}^2 L}{2p}, \quad (3.11)$$

with the oscillation amplitudes

$$I_{\alpha\beta}^{(\text{A})} \equiv 4 \text{Im}[U_{\alpha 1} U_{\beta 1}^* U_{\alpha 2}^* U_{\beta 2}] , \quad I_{\alpha\beta}^{(\text{B})} \equiv 4 \text{Im}[U_{\alpha 3} U_{\beta 3}^* U_{\alpha 4}^* U_{\beta 4}] . \quad (3.12)$$

We will now discuss the constraints on the neutrino oscillation parameters which follow from the existing results of SBL experiments. In the disappearance SBL reactor and accelerator experiments no indication in favour of neutrino oscillations was found (see the reviews in Ref. [13]). At any fixed value of Δm^2 in the range

$$0.1 \text{ eV}^2 \leq \Delta m^2 \leq 10^3 \text{ eV}^2, \quad (3.13)$$

from the exclusion plots of the Bugey [22] $\bar{\nu}_e$ disappearance experiment and of the CDHS [37] and CCFR [38] $\bar{\nu}_\mu^{(-)}$ disappearance experiments we have

$$B_{\alpha;\alpha} \leq B_{\alpha;\alpha}^0 \quad (\alpha = e, \mu). \quad (3.14)$$

Let us define the quantities c_α (with $\alpha = e, \mu, \tau$) in the two schemes A and B as

$$(A) \quad c_\alpha \equiv \sum_{k=1,2} |U_{\alpha k}|^2, \quad (3.15)$$

$$(B) \quad c_\alpha \equiv \sum_{k=3,4} |U_{\alpha k}|^2. \quad (3.16)$$

Taking also into account the results of the solar neutrino experiments and the results of the atmospheric neutrino experiments, in both schemes A and B, the quantities c_e and c_μ are constrained by [24]

$$c_e \leq a_e^0, \quad c_\mu \geq 1 - a_\mu^0, \quad (3.17)$$

where

$$a_\alpha^0 = \frac{1}{2} \left(1 - \sqrt{1 - B_{\alpha;\alpha}^0} \right) \quad (\alpha = e, \mu). \quad (3.18)$$

The values of a_e^0 and a_μ^0 which have obtained from the exclusion plots of the Bugey [22], CDHS [37] and CCFR [38] experiments are given in Fig.1 of Ref. [39]. For values of Δm^2 in the range (3.13) a_e^0 is small ($a_e^0 \lesssim 4 \times 10^{-2}$), and a_μ^0 is small for $\Delta m^2 \gtrsim 0.3 \text{ eV}^2$ ($a_\mu^0 \lesssim 10^{-1}$). In the following we will use also the limits on the amplitudes $A_{\alpha;\beta}$ which can be obtained from exclusion plots of the BNL E734 [40], BNL E776 [23] and CCFR [3] $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ appearance experiments and of the FNAL E531 [41] and CCFR [7] $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ appearance experiments:

$$A_{\alpha;\beta} \leq A_{\alpha;\beta}^0, \quad (3.19)$$

with $\alpha = \mu$ and $\beta = e, \tau$. The results of the LSND [1] $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ appearance experiment will be also taken into account (in particular, the allowed range (1.4) of Δm^2).

Since scheme B emerges from scheme A by the substitution (3.9) and since we will derive bounds on the LBL oscillation probabilities $P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL}, \text{A})}$, $P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL}, \text{B})}$ and on the CP-odd parameters $I_{\alpha\beta}^{(\text{A})}$, $I_{\alpha\beta}^{(\text{B})}$ as functions of $A_{\alpha;\beta}$, c_α and c_β , it is evident that such bounds apply equally to both schemes A and B by virtue of the definitions (3.4), (3.15) and (3.16). Consequently, when dealing with such bounds we will omit the superscripts A, B indicating the specific scheme.

IV. CONSTRAINTS ON THE LONG-BASELINE PROBABILITIES

We will consider first the limits on the LBL oscillation probabilities which can be obtained from the results of the SBL oscillation experiments. The Cauchy-Schwarz inequality implies for scheme A that

$$\left| \sum_{k=1,2} U_{\beta k} U_{\alpha k}^* \exp\left(-i \frac{\Delta m_{k1}^2 L}{2p}\right) \right|^2 \leq c_\alpha c_\beta. \quad (4.1)$$

Using this inequality and the definition (3.15) of c_α , we find from the LBL probabilities in Eqs.(3.7) and (3.8) that the survival probabilities $P_{\nu_\alpha \rightarrow \nu_\alpha}^{(\text{LBL})}$ and $P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\alpha}^{(\text{LBL})}$ are bounded by

$$(1 - c_\alpha)^2 \leq P_{\nu_\alpha \rightarrow \nu_\alpha}^{(\text{LBL})} \leq c_\alpha^2 + (1 - c_\alpha)^2. \quad (4.2)$$

As explained at the end of the last section, these bounds are scheme-independent. In order to obtain bounds on the LBL transition probabilities $P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL})}$ and $P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta}^{(\text{LBL})}$, we take into account

the definition (3.4) of $A_{\alpha;\beta}$ and the inequality (4.1). When inserted into Eqs.(3.7) and (3.8) they imply

$$\frac{1}{4} A_{\alpha;\beta} \leq P_{\nu_{\alpha} \rightarrow \nu_{\beta}}^{(\text{LBL})} \leq c_{\alpha} c_{\beta} + \frac{1}{4} A_{\alpha;\beta} . \quad (4.3)$$

The bounds (4.2) and (4.3) are the basis of the following considerations for the different oscillation channels in LBL experiments.

The smallness of c_e (see Eq.(3.17)) implies that the electron neutrino has a small mixing with the neutrinos whose mass-squared difference is responsible for the oscillations of atmospheric and LBL neutrinos (ν_1, ν_2 in scheme A and ν_3, ν_4 in scheme B). Hence, the probability of transitions of atmospheric and LBL electron neutrinos into other states is suppressed. Indeed, taking into account the constraint $c_e \leq a_e^0$, the lower bound on $P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ and the upper bounds on $P_{\bar{\nu}_{\mu} \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ which we will derive are rather strict.

Let us discuss first the bounds on the LBL survival probability $P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$. We will compare these bounds with the expected sensitivity of the CHOOZ [8] and Palo Verde [9] LBL reactor experiments. Taking into account the constraint (3.17) on c_e , Eq.(4.2) implies that in both schemes A and B

$$1 - P_{\nu_e \rightarrow \nu_e}^{(\text{LBL})} \leq a_e^0 (2 - a_e^0) . \quad (4.4)$$

The curve corresponding to this limit obtained from the 90% CL exclusion plot of the Bugey [22] experiment is shown in Fig.1 (solid line). The expected sensitivities of the LBL reactor neutrino experiments CHOOZ and Palo Verde are also shown in Fig.1 as the dash-dotted and dash-dot-dotted vertical lines, respectively. These expected sensitivities with respect to $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ have been extracted by us from the figures presented in Refs. [8,9] showing the sensitivity of the respective experiments in the $\sin^2 2\vartheta - \delta m^2$ plane, using the fact that for high values of δm^2 each experiment is sensitive only to the averaged survival probability $P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})} = 1 - \frac{1}{2} \sin^2 2\vartheta$. Thus, the vertical lines in Fig.1 correspond to $\frac{1}{2} \sin^2 2\vartheta$ at high δm^2 .

Figure 1 shows that, in the framework of the two schemes (3.1) with four neutrinos, which allow to accommodate all the indications in favour of neutrino oscillations, the existing data put rather strong limitations on the probability of LBL transitions of ν_e into other states (for $\Delta m^2 \gtrsim 3 \text{ eV}^2$ the upper bound for $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ is close to the border of the region of sensitivity of the CHOOZ experiment, whereas for $\Delta m^2 \lesssim 3 \text{ eV}^2$ it is much smaller).

The shadowed region in Fig.1 corresponds to the range (1.4) of Δm^2 allowed at 90% CL by the results of the LSND and all the other SBL experiments. It can be seen that the LSND signal indicates an upper bound for $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ of about 5×10^{-2} , smaller than the expected sensitivities of the CHOOZ and Palo Verde experiments.

Let us stress that, in the framework of the schemes under consideration, the smallness of c_e is a consequence of the solar neutrino problem. Consider for example scheme A. The probability of solar neutrinos to survive is given by

$$P_{\nu_e \rightarrow \nu_e}^{(\text{sun,A})} = \sum_{k=1,2} |U_{ek}|^4 + \left(1 - \sum_{k=1,2} |U_{ek}|^2 \right)^2 P_{\nu_e \rightarrow \nu_e}^{(3;4)} , \quad (4.5)$$

where $P_{\nu_e \rightarrow \nu_e}^{(3;4)}$ is the survival probability due to the mixing of ν_e with ν_3 and ν_4 , depending on the small mass-squared difference Δm_{43}^2 . From the results of SBL reactor experiments it follows that the quantity $c_e \equiv \sum_{k=1,2} |U_{ek}|^2$ can be small or large (close to one). In order

to have the energy dependence of the survival probability $P_{\nu_e \rightarrow \nu_e}^{(\text{sun,A})}$ and the suppression of the flux of solar ν_e 's that are required for the explanation of the data of solar neutrino experiments, we must choose a small value of c_e . In this case, the survival probability of $\bar{\nu}_e$'s in LBL reactor experiments is close to one.

Let us now discuss the bounds on $\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}$ transitions in LBL accelerator experiments. We will compare these bounds with the expected sensitivities of the KEK-Super-Kamiokande (KEK-SK) [10], Fermilab-Soudan (MINOS) [11] and CERN-Gran Sasso (ICARUS) [12] experiments.

Taking into account the constraints (3.17) on c_e and (3.19) on $A_{\mu;e}$, Eq.(4.3) implies that in both schemes A and B

$$P_{\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}}^{(\text{LBL})} \leq a_e^0 + \frac{1}{4} A_{\mu;e}^0. \quad (4.6)$$

The curve corresponding to this limit obtained from the 90% CL exclusion plots of the Bugey [22] experiment for a_e^0 and of the BNL E734 [40], BNL E776 [23] and CCFR [7] experiments for $A_{\mu;e}^0$ is shown in Fig.2 (long-dashed line). For a comparison, we have shown the expected sensitivities of the LBL accelerator neutrino experiments KEK-SK [10], MINOS [11] and ICARUS [12] (the dotted, dash-dotted and dash-dot-dotted vertical lines, respectively). These sensitivities have been obtained from the figures presented in Refs. [10–12] showing the sensitivities of the respective experiments in the $\sin^2 2\vartheta - \delta m^2$ plane with the method explained in the context of LBL reactor experiments.

The conservation of probability and Eq.(4.2) lead to a further upper bound:

$$P_{\nu_{\alpha} \rightarrow \nu_{\beta}}^{(\text{LBL})} \leq 1 - P_{\nu_{\alpha} \rightarrow \nu_{\alpha}}^{(\text{LBL})} \leq c_{\alpha} (2 - c_{\alpha}) \quad (\alpha \neq \beta). \quad (4.7)$$

CPT invariance (see Eq.(2.4)) and the fact that the bound (4.2) is valid for antineutrinos as well give the same upper bound as Eq.(4.7) for the opposite transition $\nu_{\beta} \rightarrow \nu_{\alpha}$:

$$P_{\nu_{\beta} \rightarrow \nu_{\alpha}}^{(\text{LBL})} = P_{\bar{\nu}_{\alpha} \rightarrow \bar{\nu}_{\beta}}^{(\text{LBL})} \leq 1 - P_{\bar{\nu}_{\alpha} \rightarrow \bar{\nu}_{\alpha}}^{(\text{LBL})} \leq c_{\alpha} (2 - c_{\alpha}) \quad (\alpha \neq \beta). \quad (4.8)$$

Finally, these two equations hold evidently also for antineutrinos. The solid curve in Fig.2 represents the limit

$$P_{\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}}^{(\text{LBL})} \leq a_e^0 (2 - a_e^0) \quad (4.9)$$

obtained from Eq.(4.8) and the constraint (3.17) on c_e . This bound is better than the bound (4.6) for the SBL parameter $\Delta m^2 \lesssim 0.4 \text{ eV}^2$.

The darkly shadowed area in Fig.2 represents the region allowed by the results of the LSND [1] experiment, taking into account the results of all the other SBL experiments. The lower bound on $P_{\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}}^{(\text{LBL})}$, i.e. the left edge of the shadowed region, is determined by the results

of the LSND experiment, whereas the upper bound is given by the limits obtained before, i.e. by the most stringent of the inequalities (4.9) and (4.6) represented, respectively, by the solid and long-dashed curves. Thus, for each fixed value of Δm^2 we have

$$\frac{1}{4} A_{\mu;e}^{\min} \leq P_{\nu_{\mu} \rightarrow \nu_e}^{(\text{LBL})} \leq \min \left(a_e^0 (2 - a_e^0), a_e^0 + \frac{1}{4} A_{\mu;e}^0 \right), \quad (4.10)$$

where $A_{\mu;e}^{\min}$ is the minimal value of $A_{\mu;e}$ allowed at 90% CL by the LSND experiment.

Figure 2 shows that, in the framework of the schemes under consideration, the sensitivity of the KEK-SK experiment may be not sufficient to reveal LBL $\nu_{\mu} \rightarrow \nu_e$ oscillations, whereas the sensitivities of the MINOS and ICARUS experiments are considerably better than the upper bound for $P_{\nu_{\mu} \rightarrow \nu_e}^{(\text{LBL})}$. It is interesting to observe that there is also a lower bound on this transition probability that follows from the LSND results (see Eq.(4.10)). However, this lower bound is valid only in the case of LBL neutrino oscillations in vacuum. The corrections due to the matter effects in LBL experiments make it disappear (see Section VII).

The solid curve in Fig.2 is at the same time an upper bound on $P_{\nu_e \rightarrow \nu_{\tau}}^{(\text{LBL})}$. This is evident from Eq.(4.7). On the other hand, the probability of $\nu_{\mu} \rightarrow \nu_{\tau}$ transitions is not constrained by the results of SBL experiments.

Finally, a further upper bound on $P_{\nu_{\alpha} \rightarrow \nu_{\beta}}^{(\text{LBL})}$ for $\alpha \neq \beta$ is gained from Eq.(4.3). Since $A_{\alpha;\beta} \leq 4(1 - c_{\alpha})(1 - c_{\beta})$, we have

$$P_{\nu_{\alpha} \rightarrow \nu_{\beta}}^{(\text{LBL})} \leq c_{\alpha} c_{\beta} + (1 - c_{\alpha})(1 - c_{\beta}) \quad (\alpha \neq \beta). \quad (4.11)$$

Obviously, if $c_{\alpha} = c_{\beta} = 0$ or 1 is in the allowed range of these quantities, then this upper bound is 1 and thus is trivial. This leaves only $\alpha = \mu$ and $\beta = e$ as a non-trivial case, with

$$P_{\nu_{\mu} \rightarrow \nu_e}^{(\text{LBL})} \leq a_e^0 + a_{\mu}^0 - 2a_e^0 a_{\mu}^0. \quad (4.12)$$

The short-dashed curve in Fig.2 shows this limit with a_e^0 and a_{μ}^0 obtained from the 90% CL exclusion plots of the Bugey [22] $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment and of the CDHS [37] and CCFR [38] $\bar{\nu}_{\mu} \rightarrow \bar{\nu}_{\mu}$ experiments, respectively. For $a_{\mu}^0 \ll a_e^0 \ll 1$ this bound is about half of that given by Eq.(4.9). However, since a_{μ}^0 is only small in the same range of Δm^2 where $A_{\mu;e}^0$ is small, numerically the bound (4.12) turns out to be worse than the bound (4.6) (the long-dashed curve in Fig.2).

V. CP VIOLATION IN THE SCHEMES WITH FOUR NEUTRINOS

As shown in Appendix B, the unitarity of the mixing matrix implies the “unitarity bound”

$$|I_{\alpha\beta}| \leq f(c_{\alpha}, c_{\beta}) \quad (5.1)$$

where $f(x, y)$ is the continuous function

$$f(x, y) = \begin{cases} f_1 \equiv xy & \text{for } 2(1-x)(1-y) \geq xy \\ f_2 \equiv 2[(x+y-1)(1-x)(1-y)]^{1/2} & \text{for } 2(1-x)(1-y) < xy \end{cases} \quad (5.2)$$

defined on the unit square $0 \leq x \leq 1$, $0 \leq y \leq 1$. In Fig.3 we have drawn a contour plot of the function $f(x, y)$, which is helpful for the determination of the maximal allowed value for $f(c_\alpha, c_\beta)$ when c_α and/or c_β are bounded. The dotted line in Fig.3 is the borderline $g(x) = 2(1-x)/(2-x)$ between the regions where $f = f_1$ and $f = f_2$. Note that f is continuous along this borderline.

In order to determine the maxima of $f(x, y)$, the following considerations are useful (for the details consult Appendix C). Increasing x at fixed y , the function f increases monotonously from $f = 0$ at $x = 0$, until the straight line $y_1(x) = 2 - 2x$ ($1/2 \leq x \leq 1$) depicted in Fig.3 is reached. There, the value of f is given by $f = y\sqrt{1-y}$. After this intersection, the function f decreases monotonously to $f = 0$ at $x = 1$. From the symmetry $f(x, y) = f(y, x)$, it follows that for fixed x and increasing y the function f increases monotonously from $f = 0$ at $y = 0$ to $f = x\sqrt{1-x}$ when the straight line $y_2(x) = 1 - x/2$ ($0 \leq x \leq 1$) depicted in Fig.3 is crossed. After this intersection, f decreases monotonously to $f = 0$ at $y = 1$.

The absolute maximum of the function f (see Appendix C) lies at the intersection of the lines y_1 and y_2 and is given by $f_{\max} = 2/3\sqrt{3} \approx 0.385$. Therefore, from the unitarity of the mixing matrix we have an absolute maximum for $|I_{\alpha\beta}|$:

$$|I_{\alpha\beta}| \leq \frac{2}{3^{3/2}} \approx 0.385. \quad (5.3)$$

With the help of Fig.3, one can see that Eq.(5.1) with the constraints (3.17) on c_e and c_μ implies that

$$|I_{e\mu}| \leq \begin{cases} f_2(a_e^0, y_2(a_e^0)) = a_e^0 (1 - a_e^0)^{1/2} & \text{for } a_\mu^0 \geq a_e^0/2, \\ f_2(a_e^0, 1 - a_\mu^0) = 2 [(a_e^0 - a_\mu^0) (1 - a_e^0) a_\mu^0]^{1/2} & \text{for } a_\mu^0 \leq a_e^0/2. \end{cases} \quad (5.4)$$

The solid curve in Fig.4 shows the limit $|I_{e\mu}| \leq a_e^0 \sqrt{1 - a_e^0}$ with a_e^0 obtained from the 90% CL exclusion plot of the Bugey [22] $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment. The dotted curve in Fig.4 represents the improvement reached with the lower part of Eq.(5.4) at the values of Δm^2 for which $a_\mu^0 \leq a_e^0/2$, with a_μ^0 obtained from the 90% CL exclusion plots of the CDHS [37] and CCFR [38] $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ experiments.

The bound represented by the solid curve in Fig.4 is valid also for $|I_{e\tau}|$, because there is no experimental information on c_τ .

For $|I_{\mu\tau}|$, again by inspection of Fig.3, one can see that Eq.(5.1) with the constraints (3.17) on c_μ implies that

$$|I_{\mu\tau}| \leq f_2(1 - a_\mu^0, y_2(1 - a_\mu^0)) = (1 - a_\mu^0) \sqrt{a_\mu^0}. \quad (5.5)$$

The solid curve in Fig.5 represents the corresponding bound obtained from the 90% CL exclusion curves of the CDHS [37] and CCFR [38] $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ experiments. For $\Delta m^2 \lesssim 0.3 \text{ eV}^2$ there are no experimental data and therefore $|I_{\mu\tau}|_{\max} \approx 0.385$ by virtue of Eq.(5.3).

Taking into account the expression (3.4) for $A_{\alpha;\beta}$, in both schemes A and B we have (for the proof of this inequality, see Appendix A)

$$|I_{\alpha\beta}| \leq \frac{1}{2} \sqrt{A_{\alpha;\beta} (4 c_\alpha c_\beta - A_{\alpha;\beta})} . \quad (5.6)$$

Taking into account Eq.(3.19), we obtain

$$|I_{\alpha\beta}| \leq \begin{cases} \frac{1}{2} \sqrt{A_{\alpha;\beta}^0 (4 c_\alpha c_\beta - A_{\alpha;\beta}^0)} & \text{for } A_{\alpha;\beta}^0 \leq 2 c_\alpha c_\beta , \\ c_\alpha c_\beta & \text{for } A_{\alpha;\beta}^0 \geq 2 c_\alpha c_\beta . \end{cases} \quad (5.7)$$

For $|I_{e\mu}|$, with the constraints (3.17), the inequality (5.7) becomes

$$|I_{e\mu}| \leq \begin{cases} \frac{1}{2} \sqrt{A_{\mu;e}^0 (4 a_e^0 - A_{\mu;e}^0)} & \text{for } A_{\mu;e}^0 \leq 2 a_e^0 , \\ a_e^0 & \text{for } A_{\mu;e}^0 \geq 2 a_e^0 . \end{cases} \quad (5.8)$$

The dash-dotted curve in Fig.4 shows the limit (5.8) obtained using the 90% exclusion plots of the Bugey [22] $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment for the determination of a_e^0 and the BNL E734 [40], BNL E776 [23] and CCFR [3] $\nu_\mu \rightarrow \nu_e$ experiments for the determination of $A_{\mu;e}^0$.

Since the constraints (3.17) do not put an upper bound on the possible values of c_μ and c_τ , in the case of $|I_{\mu\tau}|$ the inequality (5.7) becomes

$$|I_{\mu\tau}| \leq \frac{1}{2} \sqrt{A_{\mu;\tau}^0 (4 - A_{\mu;\tau}^0)} . \quad (5.9)$$

The dotted curve in Fig.5 shows the limit (5.9) obtained using the 90% exclusion plot of the FNAL E531 [41] and CCFR [7] $\nu_\mu \rightarrow \nu_\tau$ experiment for the determination of $A_{\mu;\tau}^0$.

The shadowed regions in Figs.4 and 5 correspond to the range (1.4) of Δm^2 allowed at 90% CL by the results of the LSND and all the other SBL experiments. From Fig.5 it can be seen that, taking into account the LSND signal, $|I_{\mu\tau}|$ could be close to the maximal value $2/3\sqrt{3}$ allowed by the unitarity of the mixing matrix.

VI. THREE MASSIVE NEUTRINOS

It is worthwhile to have a look at LBL neutrino oscillation experiments neglecting some of the present hints for neutrino oscillations. It is possible that not all these hints will be substantiated in the course of time and it is useful to check which features are actually dependent on or independent from them.

In this Section we consider the minimal scenario of mixing of three neutrinos. We will assume that of the two differences of neutrino mass-squared one is relevant for SBL oscillations and the other one for LBL oscillations (see also Refs. [26–28]). Hence, in this section we adopt the point of view that not neutrino mixing but other reasons could explain the solar neutrino data. With these assumptions, there are two possible three-neutrino mass spectra:

$$(I) \quad \underbrace{m_1 < m_2}_{\text{SBL}} \ll m_3 \quad \text{and} \quad (II) \quad m_1 \ll \underbrace{m_2 < m_3}_{\text{SBL}}, \quad (6.1)$$

In both schemes I and II, Δm_{31}^2 is assumed to be relevant for neutrino oscillations in SBL experiments. In this case, the SBL oscillation probabilities depend on $|U_{e3}|^2$ and $|U_{\mu 3}|^2$ in the scheme I [39] and on $|U_{e1}|^2$ and $|U_{\mu 1}|^2$ in the scheme II [36]. There are three regions of these quantities which are allowed by the results of disappearance experiments (see Refs. [39,36]):

$$\begin{aligned} (1) \quad & |U_{ek}|^2 \geq 1 - a_e^0, \quad |U_{\mu k}|^2 \leq a_\mu^0, \\ (2) \quad & |U_{ek}|^2 \leq a_e^0, \quad |U_{\mu k}|^2 \leq a_\mu^0, \\ (3) \quad & |U_{ek}|^2 \leq a_e^0, \quad |U_{\mu k}|^2 \geq 1 - a_\mu^0, \end{aligned} \quad (6.2)$$

with $k = 3$ for the scheme I and $k = 1$ for the scheme II² (for the definition of a_e^0 and a_μ^0 , see Eq.(3.18)).

The neutrino and antineutrino LBL oscillation probabilities in scheme I are given by

$$P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL}, I)} = \left| U_{\beta 1} U_{\alpha 1}^* + U_{\beta 2} U_{\alpha 2}^* \exp\left(-i \frac{\Delta m_{21}^2 L}{2p}\right) \right|^2 + |U_{\beta 3}|^2 |U_{\alpha 3}|^2, \quad (6.3)$$

$$P_{\bar{\nu}_\alpha \rightarrow \bar{\nu}_\beta}^{(\text{LBL}, I)} = \left| U_{\beta 1}^* U_{\alpha 1} + U_{\beta 2}^* U_{\alpha 2} \exp\left(-i \frac{\Delta m_{21}^2 L}{2p}\right) \right|^2 + |U_{\beta 3}|^2 |U_{\alpha 3}|^2. \quad (6.4)$$

From the comparison of Eqs.(6.3) and (6.4) with Eqs.(3.7) and (3.8), it is obvious that the CP-odd asymmetries $D_{\alpha;\beta}^{(\text{LBL}, I)}$ are given by the same formula (3.10) as in the 4-neutrino case (with $I_{\alpha\beta}^{(A)} \rightarrow I_{\alpha\beta}^{(I)}$). The transition probabilities in the scheme II can be obtained from the expressions (6.3) and (6.4) with the cyclic permutation of the indices

$$1, 2, 3 \rightarrow 2, 3, 1. \quad (6.5)$$

Therefore, as in the case of the schemes A and B for four neutrinos, the bounds on the LBL oscillation probabilities and the CP-odd asymmetries are the same in the three neutrino schemes I and II.

The bounds on the LBL oscillation probabilities $P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL})}$ and on the CP-odd parameters $I_{\alpha\beta}$ derived in the Appendices for the four-neutrino schemes (3.1) are valid also in the case of mixing of three neutrinos: the demonstrations in the four-neutrino case A (B) can be applied to the three neutrino case I (II) if we put $U_{\alpha 4} = 0$ ($U_{\alpha 1} = 0$ and change the indices $2, 3, 4 \rightarrow 1, 2, 3$) for all $\alpha = e, \mu, \tau$.

² For a comparison, the schemes I, II and the regions 1, 2, 3 are called hierarchies II, I and regions A, B, C, respectively, in Ref. [26].

It is obvious that, with $A_{\alpha;\beta} = 4|U_{\beta 3}|^2|U_{\alpha 3}|^2$, the same bounds on $P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL})}$ arise for $\alpha = \beta$ and $\alpha \neq \beta$ as given by Eqs.(4.2) and (4.3). Since in the 3-neutrino case the CP-odd asymmetries in different oscillation channels are connected by Eq.(2.11), we have

$$I_{e\mu} = I_{\mu\tau} = I_{\tau e} . \quad (6.6)$$

A few remarks on the unitarity bound (5.1) are in order. It is true that from the unitarity of the 3×3 mixing matrix we have $A_{\alpha;\beta} = 4(1 - c_\alpha)(1 - c_\beta)$ and $c_\alpha + c_\beta \geq 1$, but, nevertheless, the distinction defined by Eq.(B6) has to be maintained. Therefore, also the unitarity bound is upheld with the addendum that c_α and c_β can only vary within the section of the unit square defined by $c_\alpha + c_\beta \geq 1$. Since the point $c_\alpha = c_\beta = 2/3$ fulfills this condition, the absolute maximum $|I_{\alpha\beta}|_{\text{max}} = 2/3\sqrt{3}$ of the 4-neutrino case extends its validity to three neutrinos³.

In the following we will give LBL bounds for each of the regions (6.2), along the lines of the previous 4-neutrino sections.

Region 1. With respect to SBL and LBL neutrino oscillations, the 3-neutrino schemes I and II in Region 1 correspond to the 4-neutrino schemes A and B, respectively, with the same bounds on $P_{\nu_e \rightarrow \nu_e}^{(\text{LBL})}$ (Eq.(4.4) and Fig.1), $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$ (Eqs.(4.6), (4.9), (4.12) and Fig.2) and $|I_{e\mu}|$ (Eqs.(5.4), (5.8) and Fig.4). Since $|I_{\mu\tau}| = |I_{e\mu}|$, the stringent bounds on $|I_{e\mu}|$ given in Fig.4 are valid also for $|I_{\mu\tau}|$.

For completeness, we want to mention that there is a change in the upper bound for $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$ in going from four to three neutrinos: taking into account the inequality $c_e + c_\mu \geq 1$, we have $c_\mu \geq 1 - \min(a_e^0, a_\mu^0)$ and Eq.(4.12) improves to

$$P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})} \leq a_e^0 + (1 - 2a_e^0) \min(a_e^0, a_\mu^0) . \quad (6.7)$$

For $a_e^0 < a_\mu^0$ this bound is slightly more stringent than that given by Eq.(4.9), but the improvement is negligible for $a_e^0 \ll 1$.

Region 2. Actually, this Region is excluded by the results of the LSND experiment (see Refs. [39,36,24]). The reason is that (in combination with other data) the upper bound

$$A_{\mu,e} \leq 4 a_e^0 a_\mu^0 \quad (6.8)$$

is too restrictive to be compatible with the LSND data. In spite of this evidence, let us discuss the bounds on the LBL probabilities in this Region.

The restrictions $c_e \geq 1 - a_e^0$, $c_\mu \geq 1 - a_\mu^0$ and the unitarity of the mixing matrix imply that c_τ is small: $c_\tau = 2 - c_e - c_\mu \leq a_e^0 + a_\mu^0$. From Eq.(4.3) it follows that the probabilities of $\nu_\mu \rightarrow \nu_\tau$ and $\nu_e \rightarrow \nu_\tau$ transitions in LBL experiments are confined in the range

³This value is 4 times the maximal value of the Jarlskog parameter J [42] for CP violation in the Kobayashi–Maskawa matrix, $|J|_{\text{max}} = 1/6\sqrt{3}$.

$$\frac{1}{4} A_{\alpha;\tau} \leq P_{\nu_{\alpha}^{(-)} \rightarrow \nu_{\tau}^{(-)}}^{(\text{LBL})} \leq \frac{1}{4} A_{\alpha;\tau} + a_e^0 + a_{\mu}^0 \quad (\alpha = e, \mu) , \quad (6.9)$$

whereas for the probability of $\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}$ transitions we have only the lower bound

$$\frac{1}{4} A_{\mu;e} \leq P_{\nu_{\mu}^{(-)} \rightarrow \nu_e^{(-)}}^{(\text{LBL})} . \quad (6.10)$$

The inequality (4.8) yields the additional upper bounds

$$P_{\nu_{\alpha}^{(-)} \rightarrow \nu_{\tau}^{(-)}}^{(\text{LBL})} \leq (a_e^0 + a_{\mu}^0) (2 - a_e^0 - a_{\mu}^0) \quad (\alpha = e, \mu) . \quad (6.11)$$

The bounds on CP violation can be derived with the methods described in the Appendices. They are given by the oscillation amplitude bound

$$|I_{e\mu}| \leq \frac{1}{2} \sqrt{A_{\mu;e}^0 (4 - A_{\mu;e}^0)} \quad (6.12)$$

and the unitarity bound

$$|I_{e\mu}| \leq f_2(1 - a_e^0, 1 - a_{\mu}^0) = 2 \sqrt{a_e^0 a_{\mu}^0 (1 - a_e^0 - a_{\mu}^0)} . \quad (6.13)$$

Both are of similar order of magnitude and less restrictive than the bounds in Region 1. Since $|I_{\mu\tau}| = |I_{e\mu}|$, these bounds are valid also for $|I_{\mu\tau}|$.

Region 3. In this Region, where $c_e \geq 1 - a_e^0$ and $c_{\mu} \leq a_{\mu}^0$, the atmospheric neutrino data cannot be explained in the framework discussed here. The reason is that

$$P_{\nu_{\mu}^{(-)} \rightarrow \nu_{\mu}^{(-)}}^{(\text{LBL})} \geq (1 - a_{\mu}^0)^2 \quad (6.14)$$

and this is incompatible [24] with the atmospheric neutrino anomaly. The LBL transition probabilities of muon neutrinos are confined by

$$\frac{1}{4} A_{\mu;\beta} \leq P_{\nu_{\mu}^{(-)} \rightarrow \nu_{\beta}^{(-)}}^{(\text{LBL})} \leq \frac{1}{4} A_{\mu;\beta} + a_{\mu}^0 \quad (\beta = e, \tau) , \quad (6.15)$$

whereas for $\nu_e^{(-)} \rightarrow \nu_{\tau}^{(-)}$ transitions there is only the lower bound

$$\frac{1}{4} A_{e;\tau} \leq P_{\nu_e^{(-)} \rightarrow \nu_{\tau}^{(-)}}^{(\text{LBL})} . \quad (6.16)$$

The inequality (4.7), which is a consequence of probability conservation, leads to

$$P_{\nu_{\mu}^{(-)} \rightarrow \nu_{\beta}^{(-)}}^{(\text{LBL})} \leq a_{\mu}^0 (2 - a_{\mu}^0) \quad (\beta = e, \tau) . \quad (6.17)$$

Furthermore, taking into account the inequality $c_e + c_{\mu} \geq 1$, we have $c_e \geq 1 - \min(a_e^0, a_{\mu}^0)$ and Eq.(4.12) improves to

$$P_{\nu_{\mu} \rightarrow \nu_e}^{(\text{LBL})} \leq a_{\mu}^0 + (1 - 2a_{\mu}^0) \min(a_e^0, a_{\mu}^0) . \quad (6.18)$$

For $a_e^0 \ll a_{\mu}^0 \ll 1$ this bound is about half of that given by Eq.(6.17).

Finally, our methods for obtaining bounds on CP violation yield

$$|I_{e\mu}| \leq \frac{1}{2} \sqrt{A_{\mu;e}^0 (4a_{\mu}^0 - A_{\mu;e}^0)} \quad (6.19)$$

and

$$|I_{e\mu}| \leq \begin{cases} a_{\mu}^0 (1 - a_{\mu}^0)^{1/2} & \text{for } a_e^0 \geq a_{\mu}^0/2 , \\ 2 [(a_{\mu}^0 - a_e^0) (1 - a_{\mu}^0) a_e^0]^{1/2} & \text{for } a_e^0 \leq a_{\mu}^0/2 . \end{cases} \quad (6.20)$$

The oscillation amplitude bound is more stringent in this case. From Eq.(6.6) it follows that the bounds (6.19) and (6.20) are valid also for the parameter $|I_{\mu\tau}|$ that characterizes the CP-odd asymmetry in the $\nu_{\mu} \rightarrow \nu_{\tau}$ channel.

The differences in the bounds on the LBL probabilities are marked and could thus serve to distinguish between the three different Regions in the three neutrino case. Of course, in the experiments discussed here the four neutrino case (schemes A and B) is indistinguishable from the three neutrino case with Region 1. The above-mentioned distinctions could also serve as a cross-check for present hints of neutrino oscillations.

VII. CONCLUSIONS

At present there are three experimental indications in favour of neutrino oscillations which correspond to three different scales of neutrino mass-squared differences: the solar neutrino deficit, the atmospheric neutrino anomaly and the result of the LSND experiment. These indications and the negative results of numerous short-baseline neutrino experiments can be accommodated in two schemes (A and B) with mixing of four massive neutrinos [24]. In this paper we have presented a detailed study of the predictions of the schemes A and B for long-baseline experiments. Using only the results of existing experiments, we have obtained bounds on probabilities of different transitions in long-baseline experiments.

The schemes A and B give completely different predictions for neutrinoless double beta decay and for neutrino mass effects in experiments for neutrino mass measurements by the tritium method [24]. They lead, however, to the same bounds on long-baseline oscillation probabilities. In addition, all the bounds that we have derived apply for neutrinos as well as antineutrinos.

We have shown that the results of the short-baseline reactor experiment put rather severe bounds on the probability $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ of $\bar{\nu}_e$ transitions into all possible other states in long-baseline experiments. If the Δm^2 relevant in short-baseline oscillations is bigger than about 3 eV^2 , the bound on $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ is slightly higher than the sensitivity of the CHOOZ experiment, allowing some possibility to reveal neutrino oscillations in this channel. However, the results of the LSND experiment favour the range $0.3 \lesssim \Delta m^2 \lesssim 2.2 \text{ eV}^2$. We have shown that in this range the upper bound for the quantity $1 - P_{\bar{\nu}_e \rightarrow \bar{\nu}_e}^{(\text{LBL})}$ lies between 10^{-2}

and 5×10^{-2} (see Fig.1) and thus below the sensitivity of CHOOZ and Palo Verde. On the other hand, there is no restriction on $P_{\nu_\mu \rightarrow \nu_\mu}^{(\text{LBL})}$.

The probability $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$ of $\nu_\mu \rightarrow \nu_e$ transitions is severely constrained in the schemes A and B by the results of short-baseline reactor and accelerator experiments (see Fig.2). The sensitivity of MINOS and ICARUS is well below the upper bound for $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$, whereas the sensitivity of the KEK-SK experiment seems to be insufficient. There is also an upper bound on long-baseline $\nu_e \rightarrow \nu_\tau$ oscillations (solid curve in Fig.2), which is nearly as tight as the one for $\nu_\mu \rightarrow \nu_e$ transitions. On the other hand, the long-baseline $\nu_\mu \rightarrow \nu_\tau$ channel is unconstrained.

We have obtained bounds on LBL transition probabilities in the case of the neutrino mass spectra (3.1), which are implied by the results of the solar, atmospheric and LSND experiments. If the LSND data are not confirmed by future experiments, but nevertheless there is a mass (or masses) approximately equal to 1 eV providing an explanation for the hot dark matter problem, then the neutrino mass spectrum can be different from the spectra A and B in Eq.(3.1). The natural neutrino mass spectrum in this case is hierarchical and in this case the bounds that we have obtained in this paper are not valid.

In the framework of neutrino mixing in schemes A and B, we have also derived constraints on the parameters $I_{\alpha\beta}$ that characterize the CP-odd neutrino–antineutrino asymmetries in long-baseline experiments. We have developed methods for deriving upper bounds on the parameters $I_{\alpha\beta}$ from the data of short-baseline experiments, which can be applied to different schemes. We have shown that CP violation in the $\nu_\mu \rightarrow \nu_e$ channel is bounded by $|I_{e\mu}| \lesssim 10^{-2}$. A similar suppression of CP-odd effect takes place in $\nu_e \rightarrow \nu_\tau$ long-baseline neutrino oscillations. On the other hand, sizable CP violation can be expected in $\nu_\mu \rightarrow \nu_\tau$ oscillations. The CP-odd asymmetry in this channel could be close to its maximally allowed value $|I_{\mu\tau}|_{\text{max}} \approx 0.385$, resulting from unitarity of the mixing matrix.

Summarizing, we would like to emphasize that the results of all neutrino oscillation experiments lead to severe constraints on the probabilities for the probabilities for $\bar{\nu}_e$ disappearance and $\nu_\mu \rightarrow \nu_e$ and $\nu_e \rightarrow \nu_\tau$ appearance in long-baseline experiments. Nevertheless, even these channels are within the planned sensitivity of the MINOS and ICARUS experiments. The channels $\nu_\mu \rightarrow \nu_\tau$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ are not constrained at all. Therefore, from the point of view of the present investigation, long-baseline muon neutrino beams provide promising facilities for the observation of neutrino oscillations.

Let us stress that we have considered here vacuum LBL oscillations. In conclusion, we want to present some remarks about the effects of matter. In the 4-neutrino schemes under consideration active neutrinos can transform into sterile states. Therefore, not only charged current but also neutral current interactions must be taken into account [16] and the effective Hamiltonian in the flavour representation is given by

$$H_{\text{eff}} = \frac{1}{2p} \left(U \hat{M}^2 U^\dagger + \text{diag}(a_{CC}, 0, 0, a_{NC}) \right) \quad (7.1)$$

with

$$a_{CC} = 2\sqrt{2} G_F N_e p \simeq 8 \times 10^{-5} \text{ eV}^2 \left(\frac{\rho}{1 \text{ g cm}^{-3}} \right) \left(\frac{p}{1 \text{ GeV}} \right), \quad (7.2)$$

$$a_{NC} = \sqrt{2} G_F N_n p \simeq \frac{1}{2} a_{CC} \quad (7.3)$$

where $\hat{M}^2$ is the diagonal matrix of the squared masses, G_F is the Fermi constant, N_e and N_n are the electron and neutron number density⁴, respectively, and ρ is the density of matter, which in the Earth's crust is of the order of 3 g cm^{-3} . The parameters a_{CC} and a_{NC} are small with respect to the δm^2 relevant for LBL oscillations. Nevertheless, their contributions for some transitions can be important (see [28] for the case of three neutrinos).

In order to take into account the matter effects in the oscillation probabilities we must diagonalize H_{eff} ⁵. In the case of the schemes (3.1) under consideration, the relation $a_{CC} \ll \Delta m^2 \sim 1 \text{ eV}^2$ is valid and thus, up to terms of the order $a_{CC}/\Delta m^2$, we have

$$H_{\text{eff}} = U' \frac{\hat{\epsilon}}{2p} U'^{\dagger} \quad (7.4)$$

where $\hat{\epsilon} = \text{diag}(\epsilon_1, \dots, \epsilon_4)$, $U' = UR$ and R has the block structure

$$R = \begin{pmatrix} R' & 0 \\ 0 & R'' \end{pmatrix}. \quad (7.5)$$

The matrices R' and R'' are 2×2 unitary matrices. Now instead of Eq.(3.7) we obtain for the LBL oscillation probabilities

$$P_{\nu_\alpha \rightarrow \nu_\beta}^{(\text{LBL})} = \left| \sum_{j=1,2} U'_{\beta j} U_{\alpha j}^* \exp \left(-i \frac{\epsilon_j}{2p} L \right) \right|^2 + \left| \sum_{k=3,4} U'_{\beta k} U_{\alpha k}^* \exp \left(-i \frac{\epsilon_k}{2p} L \right) \right|^2. \quad (7.6)$$

From the Cauchy–Schwarz inequality it is easy to see that in both schemes A and B the upper bounds (4.2), (4.11) and therefore (4.12) (represented by the short-dashed curve in Fig.2) are valid in the case of matter apart from corrections of the order of $a_{CC}/\Delta m^2$. Other bounds could be modified by the matter effect.

However, the upper bound (4.4) applied to reactor LBL experiments is practically not modified by matter effects. In fact, the relevant parameter $\epsilon_4 - \epsilon_3 \sim a_{CC} L / 2p \approx 0.5 \times 10^{-6} (L/1 \text{ m})$, for $\rho = 3 \text{ g cm}^{-3}$, is around 10^{-4} for CHOOZ and Palo Verde, whereas in the case of MINOS and ICARUS it is not small ($a_{CC} L / 2p \approx 0.4$). For the KEK-SK experiment, matter corrections are still modest because the baseline is roughly a factor of three smaller than the baseline of MINOS and ICARUS. Due to matter effects the bounds (4.6) and (4.9) on the $\nu_\mu \rightarrow \nu_e$ transition probability depicted in Fig.2 become less restrictive, in particular for the MINOS and ICARUS experiments. Note that also because matter induces corrections of the order of 10^{-2} the lower bound obtained in the vacuum case from the results of the LSND experiment (the left borderline of the darkly shadowed area in Fig.2) disappears and the lightly shadowed region in Fig.2 is allowed by the LSND experiment in the case of LBL

⁴ $N_e \simeq N_n \simeq \frac{N_A}{2} \frac{\rho}{1 \text{ g}}$, where N_A is the Avogadro number.

⁵ Here we consider the simplifying approximation of constant N_e and N_n .

oscillations in matter. A detailed discussion of matter effects in the case of mixing of four massive neutrinos will be published elsewhere [43].

For antineutrinos the relevant effective Hamiltonian is obtained from Eq.(7.1) by taking U^* instead of U and putting a minus in front of a_{CC} and a_{NC} . Therefore, matter effects can mimic CP-odd asymmetries and at least at the order of 10^{-2} both effects are entangled. In the framework of the schemes with mixing of three neutrinos the effects of matter in long-baseline experiments were considered recently in Refs. [26–28]. It was shown that the contribution of matter to the CP-odd asymmetries is small for all transitions, except for $\nu_\mu \rightarrow \nu_e$ transitions in the Region 2 of the scheme I [28], which is not compatible with the LSND result [39].

APPENDIX A: DERIVATION OF THE OSCILLATION AMPLITUDE BOUND

In this Appendix we discuss the derivation of the “oscillation amplitude bound”. The starting point is the quantity

$$I_{\alpha\beta} = 4 \operatorname{Im}[U_{\alpha 1} U_{\beta 1}^* U_{\alpha 2}^* U_{\beta 2}] \quad (\alpha \neq \beta) , \quad (\text{A1})$$

which determines the CP-odd asymmetry in the case of four massive neutrinos.

It is obvious that $I_{\alpha\beta}$ is invariant under the phase transformation

$$U_{\alpha j} \rightarrow e^{i\gamma_j} U_{\alpha j} , \quad U_{\beta j} \rightarrow e^{i\gamma_j} U_{\beta j} , \quad (\text{A2})$$

where the γ_j are arbitrary phases. Thus the elements $U_{\alpha j}$ can be taken to be real. Taking into account the definitions (3.15) and (3.16) valid in the schemes A and B of Eq.(3.1), respectively, we can write

$$U_{\alpha j} = \sqrt{c_\alpha} e_j^{(1)} , \quad \text{with} \quad \begin{cases} j = 1, 2 & \text{in the scheme A,} \\ j = 3, 4 & \text{in the scheme B,} \end{cases} \quad (\text{A3})$$

and the orthonormal basis

$$e^{(1)}(\theta) = (\cos \theta, \sin \theta) , \quad e^{(2)}(\theta) = (-\sin \theta, \cos \theta) . \quad (\text{A4})$$

We expand $U_{\beta j}$ (with $j = 1, 2$ in the scheme A and $j = 3, 4$ in the scheme B) with respect to this basis as

$$U_{\beta j} = \sqrt{c_\beta} \sum_{\rho=1,2} p_\rho e_j^{(\rho)} , \quad (\text{A5})$$

where p_1 and p_2 are complex coefficients such that

$$\sum_{\rho=1,2} |p_\rho|^2 = 1 . \quad (\text{A6})$$

With the help of Eqs.(A3)–(A6) we easily find

$$I_{\alpha\beta} = 2 c_\alpha c_\beta \sin 2\theta \operatorname{Im}(p_1^* p_2) = 2 c_\alpha c_\beta |p_1| \sqrt{1 - |p_1|^2} \sin 2\theta \sin \delta , \quad (\text{A7})$$

where δ is the phase of $p_1^* p_2$.

The parameter $|p_1|$ is connected to the oscillation amplitude $A_{\alpha;\beta}$ and the parameters c_α, c_β . In fact, from Eqs.(A3) and (A5) we have

$$A_{\alpha;\beta} = \begin{cases} 4 \left| \sum_{j=1,2} U_{\alpha j} U_{\beta j}^* \right|^2 = 4 c_\alpha c_\beta |p_1|^2 & \text{in the scheme A ,} \\ 4 \left| \sum_{j=3,4} U_{\alpha j} U_{\beta j}^* \right|^2 = 4 c_\alpha c_\beta |p_1|^2 & \text{in the scheme B .} \end{cases} \quad (\text{A8})$$

Hence, in both schemes A and B, we have $|p_1| = \sqrt{A_{\alpha;\beta}/4c_\alpha c_\beta}$. Inserting this value in Eq.(A7), we obtain

$$I_{\alpha\beta} = \frac{1}{2} \sqrt{A_{\alpha;\beta} (4 c_\alpha c_\beta - A_{\alpha;\beta})} \sin 2\theta \sin \delta \quad (\text{A9})$$

and thus we arrive at the “oscillation amplitude bound”

$$|I_{\alpha\beta}| \leq \frac{1}{2} \sqrt{A_{\alpha;\beta} (4 c_\alpha c_\beta - A_{\alpha;\beta})} . \quad (\text{A10})$$

Let us stress that this derivation is based only on the obvious inequality

$$|\sin 2\theta \sin \delta| \leq 1 . \quad (\text{A11})$$

Since c_α , c_β and $A_{\alpha;\beta}$ do not restrict θ and δ , the bound (A10) is the optimal one.

APPENDIX B: DERIVATION OF THE UNITARITY BOUND

Up to now we did not use the unitarity of the mixing matrix. Taking this fact into account will allow us to obtain an upper bound on $|I_{\alpha\beta}|$ depending solely on c_α and c_β .

The unitarity of the mixing matrix tells us that

$$\sum_{j=1,2} U_{\alpha j} U_{\beta j}^* = - \sum_{j=3,4} U_{\alpha j} U_{\beta j}^* . \quad (\text{B1})$$

This relation allows to write the oscillation amplitude $A_{\alpha;\beta}$ in the two forms of Eq.(3.4). Using the Cauchy–Schwarz inequality, one can see that

$$A_{\alpha;\beta} = 4 \left| \sum_{j=3,4} U_{\alpha j} U_{\beta j}^* \right|^2 \leq 4 \left(\sum_{j=3,4} |U_{\alpha j}|^2 \right) \left(\sum_{j=3,4} |U_{\beta j}|^2 \right) = 4 (1 - c_\alpha) (1 - c_\beta) , \quad (\text{B2})$$

in the scheme A, and

$$A_{\alpha;\beta} = 4 \left| \sum_{j=1,2} U_{\alpha j} U_{\beta j}^* \right|^2 \leq 4 \left(\sum_{j=1,2} |U_{\alpha j}|^2 \right) \left(\sum_{j=1,2} |U_{\beta j}|^2 \right) = 4 (1 - c_\alpha) (1 - c_\beta) , \quad (\text{B3})$$

in the scheme B. Hence, in both schemes A and B the oscillation amplitude $A_{\alpha;\beta}$ is bounded by

$$A_{\alpha;\beta} \leq 4 (1 - c_\alpha) (1 - c_\beta) . \quad (\text{B4})$$

The right-hand side of the inequality (A10), as a function of $A_{\alpha;\beta}$, reaches its maximum, $c_\alpha c_\beta$, at

$$(A_{\alpha;\beta})_0 = 2 c_\alpha c_\beta . \quad (\text{B5})$$

Consequently, if the condition

$$2(1 - c_\alpha)(1 - c_\beta) \geq c_\alpha c_\beta \quad (\text{B6})$$

is satisfied, the upper bound (B4) on $A_{\alpha;\beta}$ is larger than $(A_{\alpha;\beta})_0$. In this case we have

$$|I_{\alpha\beta}| \leq c_\alpha c_\beta . \quad (\text{B7})$$

If the condition (B6) is not fulfilled, the upper bound (B4) is smaller than $(A_{\alpha;\beta})_0$ and has to be inserted for $A_{\alpha;\beta}$ into Eq.(A10), leading to

$$|I_{\alpha\beta}| \leq 2 \sqrt{(c_\alpha + c_\beta - 1)(1 - c_\alpha)(1 - c_\beta)} . \quad (\text{B8})$$

Thus, we arrive at the “unitarity bound”

$$|I_{\alpha\beta}| \leq f(c_\alpha, c_\beta) , \quad (\text{B9})$$

with the function

$$f(x, y) = \begin{cases} f_1 \equiv xy & \text{for } 2(1-x)(1-y) \geq xy , \\ f_2 \equiv 2[(x+y-1)(1-x)(1-y)]^{1/2} & \text{for } 2(1-x)(1-y) < xy , \end{cases} \quad (\text{B10})$$

defined on the unit square $0 \leq x \leq 1, 0 \leq y \leq 1$. The function

$$g(x) = \frac{2(1-x)}{2-x} \quad (\text{B11})$$

represents the borderline separating the two regions in the definition of the function (B10). It is clear from our derivation (and also easy to check) that f is continuous along this borderline.

APPENDIX C: DISCUSSION OF THE FUNCTION f

Since we do not have definite experimental values of c_α and c_β , but only bounds on these quantities (see Eq.(3.17)), which define allowed rectangles in the square $0 \leq c_\alpha \leq 1, 0 \leq c_\beta \leq 1$, we are interested in the behaviour of f in order to evaluate the unitarity bound.

From the partial derivative of f in the region $y \geq g(x)$,

$$\frac{\partial f}{\partial x} = \frac{\partial f_2}{\partial x} \propto (2 - 2x - y) , \quad (\text{C1})$$

one can see that, at fixed y , the function f increases monotonously from $x = 0$ to the point $x = 1 - y/2$, where the partial derivative in Eq.(C1) is zero. The points $x = 1 - y/2$ lie on the straight line $y_1(x) = 2 - 2x$. In the range $1 - y/2 \leq x \leq 1$ the function f decreases monotonously. Taking into account the symmetry $f(x, y) = f(y, x)$, we see that at fixed x the function f increases monotonously from $y = 0$ to the point $y = 1 - x/2$, where the partial derivative of f with respect to y is zero. These points lie on the straight line $y_2(x) = 1 - x/2$. Beyond this line f decreases monotonously. Note that both straight lines lie in the range of f_2 .

Figure 3 shows a contour plot of the function $f(x, y)$, together with the lines y_1 and y_2 which intersect at the point

$$x = y = \frac{2}{3} . \tag{C2}$$

At this point both partial derivatives of f are equal to zero and therefore the point (C2) corresponds to the absolute maximum of f , given by

$$f_{\max} = f_2\left(\frac{2}{3}, \frac{2}{3}\right) = \frac{2}{3^{3/2}} \approx 0.385 . \tag{C3}$$

This number constitutes the absolute upper bound for $|I_{\alpha\beta}|$.

FIGURES

FIG.1. Upper bound for the transition probability of LBL reactor $\bar{\nu}_e$'s into all possible states, $1 - P_{\nu_e \rightarrow \nu_e}^{(\text{LBL})}$, for the SBL Δm^2 in the range $10^{-1} \text{ eV}^2 \leq \Delta m^2 \leq 10^3 \text{ eV}^2$. The solid curve is obtained from the 90% CL exclusion plot of the Bugey $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment (see Eq.(4.4)). The dash-dotted and dash-dot-dotted vertical lines depict, respectively, the expected sensitivities of the CHOOZ and Palo Verde LBL reactor neutrino experiments. The shadowed region corresponds to the range of Δm^2 allowed at 90% CL by the results of the LSND experiment, taking into account the results of all the other SBL experiments (see Eq.(1.4)).

FIG.2. Upper bound for the probability of $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ transitions in LBL experiments. The solid curve is obtained only from the 90% CL exclusion plot of the Bugey $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment (see Eq.(4.9)), whereas for the long-dashed curve the 90% CL exclusion plots of the BNL E734, BNL E776 and CCFR $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ experiments (see Eq.(4.6)) and for the short-dashed curve the 90% CL exclusion plots of the CDHS [37] and CCFR [38] $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ experiments (see Eq.(4.12)) have been used in addition. The dotted, dash-dotted and dash-dot-dotted vertical lines represent, respectively, the expected sensitivities of the LBL accelerator neutrino experiments KEK-SK, MINOS and ICARUS. The darkly shadowed region is allowed by the results of the LSND experiment, taking into account the results of all the other SBL experiments, in the case of LBL oscillations in vacuum. The two horizontal borderlines correspond to the limits (1.4) for Δm^2 and the left borderline corresponds to the lower bound in Eq.(4.10). The lightly shadowed region is allowed by the results of the LSND and all the other SBL experiments in the case of LBL oscillations in matter. The solid curve constitutes also an upper bound for the probability of $\nu_e \rightarrow \nu_\tau$ and $\bar{\nu}_e \rightarrow \bar{\nu}_\tau$ transitions.

FIG.3. Contour plot of the function $f(x, y)$ given in Eq.(5.2). The dotted line is the borderline $g(x) = 2(1 - x)/(2 - x)$ between the regions where $f = f_1$ and $f = f_2$. The two solid lines represent the functions $y_1(x) = 2 - 2x$ and $y_2(x) = 1 - x/2$.

FIG.4. Upper bound for the parameter $|I_{e\mu}|$ which characterizes the CP-odd asymmetry in the $\nu_\mu \rightarrow \nu_e$ channel for the SBL parameter Δm^2 in the range $10^{-1} \text{ eV}^2 \leq \Delta m^2 \leq 10^3 \text{ eV}^2$. The solid curve represents the upper function in Eq.(5.4) and is obtained from the 90% CL exclusion plot of the Bugey $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment. The dotted curve improves the solid curve where $a_\mu^0 \leq a_e^0/2$ (the lower function in Eq.(5.4)). It is obtained from the 90% CL exclusion plots of the Bugey $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment and the CDHS and CCFR $\nu_\mu \rightarrow \nu_\mu$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ experiments. The dash-dotted curve is obtained from the 90% CL exclusion plots of the Bugey $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiment and the BNL E734, BNL E776 and CCFR $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ experiments (see the upper function in Eq.(5.8)). The shadowed region corresponds to the range (1.4) of Δm^2 allowed at 90% CL by the results of the LSND experiment. The solid curve represents also an upper bound for $|I_{e\tau}|$.

FIG.5. Upper bound for the parameter $|I_{\mu\tau}|$ which characterizes the CP-odd asymmetry in the $\nu_\mu \rightarrow \nu_\tau$ channel. The solid curve is obtained from the 90% CL exclusion plots of the CDHS and CCFR $\nu_\mu \rightarrow \nu_\mu$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$ experiments (see Eq.(5.5)). The dotted curve is obtained from the 90% CL exclusion plots of the FNAL E531 and CCFR $\nu_\mu \rightarrow \nu_\tau$ experiments (see Eq.(5.9)). The shadowed region corresponds to the range (1.4) of Δm^2 allowed at 90% CL by the results of the LSND experiment.
